Abstract

Objectives: Since December 2016, Brazil has experienced an unusually large outbreak of yellow fever (YF). Whether urban transmission may contribute to the extent of the outbreak is unclear. The objective of this study was to characterize YF virus (YFV) genomes and to identify spatial patterns to determine the distribution and origin of YF cases in Minas Gerais, Espírito Santo and Rio de Janeiro, the most affected Brazilian states during the current YFV outbreak.

Methods: We characterized near-complete YFV genomes from 14 human cases and two nonhuman primates (NHP), sampled from February to April 2017, retrieved epidemiologic data of cases and used a geographic information system to investigate the geospatial spread of YFV.

Results: All YFV strains were closely related. On the basis of signature mutations, we identified two cocirculating YFV clusters. One was restricted to the hinterland of Espírito Santo state, and another formed a coastal cluster encompassing several hundred kilometers. Both clusters comprised strains from humans living in rural areas and NHP. Another NHP lineage clustered in a basal relationship. No signs of adaptation of YFV strains to human hosts were detected.

Conclusions: Our data suggest sylvatic transmission during the current outbreak. Additionally, cocirculation of two distinct YFV clades occurring in humans and NHP suggests the existence of multiple sylvatic transmission cycles. Increased detection of YFV might be facilitated by raised awareness for arbovirus-mediated disease after Zika and chikungunya virus outbreaks. Further surveillance is required, as reemergence of YFV from NHPs might continue and facilitate the appearance of urban transmission cycles.

Introduction

Since December 2016, Brazil has been affected by an unusually large and expanding yellow fever (YF) outbreak, with over 3500 suspected cases reported and several hundred deaths [1]. Descriptive epidemiologic evidence suggests that the outbreak so far shows a sylvatic transmission pattern, with human infections being acquired from nonhuman primates (NHP) via forest-associated mosquito species [1]. However, recent research has identified urban mosquito vectors to be competent for transmission of YF virus (YFV),
suggesting a risk of reemergence of urban YF in Brazil [2]. In the context of the present outbreak, only two complete NHP YFV genomes from a single geographic location have been sequenced so far [3]. The lack of genome data is of concern for public health, as it hinders the distinction between sylvatic YF that is endemic in Brazil [4] and urban YF that would require high-priority public health interventions. To elucidate transmission cycles, we aimed to phylogenetically characterize YFV strains from three of the most affected Brazilian states.

Methods

Human specimens were sent for diagnostics by attending physicians. NHP samples were sent within flavivirus surveillance programs to the Flavivirus Reference Laboratory of the Oswaldo Cruz Institute. Genomic sequencing of YFV strains is routinely done to differentiate between wild-type YFV infection and vaccine-associated adverse effects [5]. The study was approved by the institutional research ethics board under protocol IOC 274/05. Samples originated in the states of Minas Gerais (MG), Espírito Santo (ES) and Rio de Janeiro (RJ), areas massively affected by YF since 2016 [6]. YFV infection was confirmed by real-time RT-PCR [7]. YFV genomes were amplified by overlapping nested RT-PCR assays and were Sanger sequenced (Supplementary Table S1).

Results

The median age of human patients was 43 years (range, 1.5—71 years). A total of 71.4% of the affected subjects lived in rural areas (Table 1). Adult age and rural origin of the cases in this study were consistent with data from Brazilian authorities identifying rural workers aged 20 to 43 years as the most exposed group during the current YF outbreak [1,8]. Only four subjects lived in urban areas (Table 1). Adult age and rural origin of the cases in this study were consistent with data from Brazilian authorities identifying rural workers aged 20 to 43 years as the most exposed group during the current YF outbreak [1,8]. Only four subjects lived in urban areas. All viruses detected clustered in a distinct sister clade to YFV strains obtained from humans and NHP in Brazil and Venezuela between 2000 and 2010 (Fig. 1(A)). From one of the human cases previously described strains were genetically closely related [3]. In our larger data set, 55 synonymous (ds) and 27 nonsynonymous (dn) exchanges were observed between YFV outbreak strains (Fig. 1(C)). Whether any of the mutations in the outbreak strains or a combination thereof may alter the virus phenotype will therefore require careful investigation.

To further elucidate transmission cycles, we analysed the morphic sites within all YFV strains from this study as well as the two previously published strains [3]. As shown in Fig. 1(D), six clades could be differentiated by unique mutations. Three YFV strains from human cases (termed 2–4 in Fig. 1(D)) showed unique mutations that were not shared by any other virus. This pattern might be expected upon human-to-human transmission. However, these three lineages showed relatively high mutual sequence distances of nine to 16 nucleotide exchanges located in different parts of the virus genome. This spoke against their evolution during human-to-human transmission and instead suggested a common source of all viruses in YFV. Two larger viral clades (termed 5 and 6 in Fig. 1(D)) contained signature mutations in the nonstructural domains NS2b, NS3, NS4b and NS5, irrespective of strain origin from humans or NHP. No evidence for site-specific diversifying selection was observed in human YFV strains [9]. The mean dn/ds ratio in the complete data set was low, at 0.14 (95% confidence interval, 0.08–0.23), which was similar to a previous analysis showing strong purifying selection in YFV [10]. Clade 5 appeared to

be restricted to a region in the hinterland of the ES state (Fig. 1(E) and (F)). In contrast, clade 6 contained viruses sampled across distances exceeding 200 km along the Brazilian coast (Fig. 1(E) and (F)).

Discussion

A striking attribute of the current YF outbreak is its geographic extension, with cases having been reported across 2000 km [1]. This vast extent would be most compatible with human movement and transmission, as suggested by phylogeographic analyses indicating that the currently circulating YFV strain may have originated from an ancestor imported to Brazil from Trinidad and Tobago [11]. Although limitations of our study include the restricted geographical coverage that precludes geographically representative conclusions, the coastal distribution of one of the YFV clusters we observed may be consistent with virus transfer aided by human movement.

However, our molecular and epidemiologic data were not supportive of predominantly human-to-human transmission. Instead, the rural origin of the human cases in our study, together with the lack of signal for molecular adaptation of YFV strains to human hosts, suggested predominantly sylvatic transmission and maintenance. This has been observed in shorter time spans during epidemics, and it is believed that in situ maintenance shapes the evolutionary dynamics of YFV genotype I [11]. Additionally, cocirculation of two distinct YFV clades occurring in humans and NHP at the same time suggests parallel existence of multiple sylvatic transmission cycles. Geographically representative genomic data sets will be needed from human cases, NHP and potential mosquito vectors involved in sylvatic or urban cycles [2,12,13] to permit assessments of other YF foci that were not covered in our study, and discover if human-to-human transmission plays a role in YFV dissemination.

Finally, we cannot exclude a reporting bias, potentially causing unrelated sylvatic foci to be confused with a large contiguous outbreak. Hypothetically, such a reporting bias may be caused by raised awareness for arbovirus infections due to the Zika and chikungunya virus outbreaks affecting Brazil during the last years [14]. Brazil is responding to the outbreak by large vaccination programmes, which will be required to prevent further expansion and potential reoccurrence of urban cycles [15].
